ABSTRACT

Spontaneous pneumothorax (SP) is a very rare condition, mainly seen in patients with underlying lung diseases. Pneumothorax caused by lung metastasis occurs in 1% of whole spontaneous pneumothorax cases, especially in the setting of cytotoxic chemotherapy or radiotherapy. The most frequently involved tumor is osteogenic sarcoma. But, before initiation of chemotherapy, spontaneous pneumothorax as a complication of malignancy is rare. Herein, we report a case of spontaneous pneumothorax in a 19-year-old female with osteosarcoma of left ilium. The patient was not receiving chemotherapy or radiotherapy and was found to have pneumothorax at the initial presentation, which is rare. Chest CT revealed bilateral pulmonary metastases and right sided pneumothorax.

Keywords: Spontaneous pneumothorax, Pulmonary metastases, Osteosarcoma, Multiple random nodules, Chemotherapy.

INTRODUCTION

Spontaneous pneumothorax (SP) can be encountered with various lung tumors: primary tumors, metastasis, lymphangitis carcinomatosis. Only about 1% of SP are due to lung metastasis. Approximately 80% of secondary spontaneous pneumothorax cases are associated with metastatic osteogenic sarcoma. It occurs after initiation of chemotherapy or radiotherapy due to necrosis of subpleural metastases. Pneumothorax decreases the quality of life and increases the risk of mortality in osteosarcoma patients. Only less than 10% of osteosarcoma patients with SP survive for >2 years following the initial diagnosis of pneumothorax patients. We hereby, report a case of spontaneous pneumothorax in a 19-year-old female due to metastatic osteosarcoma of left iliac bone.

CASE REPORT

A 19-year-old female presented with dyspnea for 2 days. She had no history of trauma or any surgical intervention in the chest region. She had no other complaints like history of fever, chest pain, hemoptysis. She had no significant medical or surgical history. She had swelling above left hip joint associated with mild pain for 1 year, for which she was under treatment by a local doctor who diagnosed it as muscular swelling but no improvement was noted after conservative management. Due to mild pain patient ignored it and then the patient developed sudden onset of respiratory distress for which she was admitted to our institution. On examination, pulse rate was 94 bpm and regular; respiratory rate 36/min, BP-124/80 mmHg. No central cyanosis or clubbing was not present. Chest examination showed tympanic percussion note and diminished vesicular breath sound over right hemithorax. On local examination, a huge soft tissue swelling noted in left hip region. No warmth or tenderness was noted. She was referred to our department for urgent chest X-ray. However, CXR was apparently normal without any evidence of lung nodules or pneumothorax. CT scan of thorax was done which revealed right pneumothorax with multiple pulmonary nodules in bilateral lung fields. Computed tomography of pelvis showed a soft tissue mass lesion centered on left hemipelvis with calcific foci. Sunburst type of periosteal reaction of ilium was noted. MRI of the pelvis revealed heterogeneous mass lesion in left iliac bone with soft tissue extension, possibly osteosarcoma. Punch biopsy from the lesion revealed osteosarcoma. She was referred to our regional cancer center for further management.
DISCUSSION

Pneumothorax can be spontaneous (non-traumatic), traumatic or iatrogenic. SP can be primary (without any pre-existing lung pathology) or secondary (with abnormal underlying lung). SP is usually seen in healthy young males, its pathogenesis is associated with rupture of bullae, blebs, and subpleural emphysema. SP also occurs secondary to pulmonary disorders like chronic obstructive pulmonary disease (COPD), diffuse interstitial fibrosis, infections, iatrogenic factors like mechanical ventilation, central line in the subclavian vein, tracheostomy and due to chest trauma. There is a known association between emphysematous pulmonary bullae and lung cancer, but this very rarely predisposes to pneumothorax as the initial clinical manifestation, 0.03% being the incidence due to the primary lung tumour and with that of pulmonary metastases is even rarer. Lung is the most frequent site for metastasis of osteosarcoma. The mechanism of pneumothorax is not clearly understood yet, several hypotheses have been proposed:

1. Formation of a fistula between parenchyma and pleura due to rupture of necroticsubpleural tumor nodule or micrometastasis, secondary to vascular lesion or chemotherapy or radiotherapy.
2. Ball-valve mechanism due to partial bronchiolar obstruction by a tumor tissue, causing alveolar distension, dehiscence of alveolar walls, and passage of air in the interlobular septa to the pleura, forming blebs that breaks.
3. Tumor emboli with infarction and necrosis.
4. Tumor infiltration in the wall of a preexisting benign cavity and its rupture into the pleural space. Pneumothorax can be one-sided or simultaneous bilateral in patients with osteosarcoma, those receiving chemotherapy have a higher incidence than those who do not. The relative risk of pneumothorax developing doubled, from 7–14%, after the introduction of chemotherapy. The period
CONCLUSION

Although the pathogenesis of spontaneous pneumothorax is not clear, we conclude that the metastases as random nodules in lung parenchyma and under the pleura and their cystic degeneration can lead to spontaneous pneumothorax. Chest computed tomography detects minimal pneumothorax or subpleural lung metastasis and early diagnosis and management can help improve the prognosis and the quality of life of the patient. It can also be stressed that patients presenting with spontaneous pneumothorax without any known lung pathology should be actively investigated for metastatic neoplasm.

Acknowledgements

We would like to thank Dr. Sanjay Kumar Nahak, Senior Resident, Department of Radio-diagnosis, SCB medical college for providing an MRI image of this case. The authors would also like to thank the patient and her father for their cooperation.
