ABSTRACT

Background: This was a prospective observational study was carried out in Shaheed Shaikh Abu-Naser Specialized Hospital, Khulna, Bangladesh during the period from January 2017 to December 2018. Our aim was to evaluate left ventricular diastolic dysfunction in congestive heart failure resulting from systemic hypertension. **Methods:** Fifty patients with systemic hypertension who had recently experienced CHF with normal ejection fraction ($\geq 50\%$) and no clinical history of ischaemic cardiomyopathy were studied. The patients were divided into two groups according to the degree of echocardiographic hypertrophy: group-I (26 patients) with a ventricular mass/volume ratio >1.8 and group-II (24 patients) with a ratio <1.8 . **Results:** Group I patients had a higher ejection fraction (67.62 ± 3.14 vs 55.33 ± 4.13 , $P < 0.001$), smaller ventricular diameter (28.88 ± 2.46 vs 34.38 ± 4.37 , $P < 0.001$), higher LV mass (154.42 ± 6.80 vs 123.38 ± 5.58 , $P < 0.001$), lower ETT positivity (15% vs 75% , $P < 0.001$). Clinically, group I had more frequent audible fourth heart sound (57% vs 20% , $P < 0.001$), low incidence of audible third heart sound (15% vs 70% , $P < 0.001$), ECG evident LVH mass (96% vs 16% , $P < 0.001$), cardiomegaly (23% vs 70% , $P < 0.001$). **Conclusion:** There were no significant differences between groups for NYHA class, age, sex, heart rates and systolic blood pressure but significantly associated with Diastolic BP, ECG (LVH) and Cardiomegaly.

Keywords: Diastolic Dysfunction, Congestive Heart Failure, Systematic Hypertension.

INTRODUCTION

Cardiac cycle consists of both systole and diastole, and the classical syndrome of congestive heart failure, may be either due to systolic dysfunction or diastolic dysfunction or both. Congestive heart failure (CHF) with normal left ventricular systolic function an abnormal diastolic function is a common clinical entity. Typically, signs and symptoms are indistinguishable from those of heart failure related to systolic dysfunction (Paul et al. 1996). Coronary artery disease, systemic hypertension and aging are all associated with diastolic congestive heart failure (DCHF) (Spencer and Lang 1997). In cases of CHF in elderly patients, the prevalence of left ventricular failure with normal ejection fraction is as high as 30-40 percent (Echeverria et al. 1983; Dougherty et al. 1984; Souer et al. 1985; Kessler 1988) with arterial hypertension being the most frequent etiologic cause (Echeverria et al. 1983; Dougherty et al. 1984).

Several factors predispose to increased diastolic stiffness in a left ventricle with normal systolic performance. These include fibrosis, pericardial constriction and myocardial restriction (Bonow et al. 1992). Diastolic dysfunction is caused by at least two distinct, yet interrelated. Properties of the heart: the passive elastic properties and active relaxation of the myocardium (Paul et al. 1996). With the loss of elastic properties of the heart, there is reduction in compliance and with impairment of relaxation; there is an increase in myocardial wall tension during diastole, both of which cause increased pulmonary venous pressure. The most common condition in which these factors conspire to elevate filling pressure is hypertension. Loss of elastic properties in hypertension leading to abnormal diastolic function results from the effect of hypertrophy and increase in collagen network of the myocardium. Weber et al. (1994) described the dynamic collagen turnover in the myocardium Collagen. With a high tensile strength, is a major determinant of chamber stiffness, Factors that appears to contribute to the appearance of myocardial fibrosis through their effects as collagen turnover include hormones of the renin-angiotensin-aldosterone system, endothelia and bradykinin (Weber and Brilla 1991). Besides this,

impaired active relaxation also contributes to the path physiology of ventricular diastolic dysfunction, resulting from systemic hypertension, coronary artery disease and aging. Congestive heart failure caused by abnormal diastolic function may be far more common than previously recognized. The diastolic disorder must be distinguished from systolic abnormalities because treatment is significantly different. A history of myocardial infarction, cardiomegaly, Q-wave on the electrocardiogram and an S₃ gallop favours systolic dysfunction. However, an S₄ gallop, left ventricular hypertrophy and normal cardiac size favour diastolic function' However, there is overlap since the disease may produce either or both' Clinical assessment without cardiac imaging is, therefore, incomplete and inaccurate in many cases (Goldsmith and Dich 1993). To accurately distinguish between systolic and diastolic dysfunction, left ventricular function must be assessed. This can be accomplished with echocardiography, radionuclide angiography or radiographic ventriculography.

Source: Google

Echocardiography appears great adventurous because of its portability and lack of radiation as well as its ability to evaluate valvular function, pericardial status, wall motion and chamber hypertrophy. Ideally the diagnosis should be confirmed by documenting elevation of left ventricular diastolic pressure, but this is often impractical. Therefore, noninvasive procedures such as radionuclide and echocardiogram studies to be widely used. While radionuclide angiography is a powerful tool for excluding left ventricular systolic dysfunction, its use for diagnosing diastolic dysfunction is limited (Spencer and Lang 1997) Doppler echocardiography, a noninvasive and simple procedure, provides insight into left ventricular diastolic dysfunction (Appleton et al. 188; Appleton 1993; Pai and Buech 1996). The most commonly used Doppler parameters of Diastolic dysfunction are derived from left ventricular inflow and pulmonary venous inflow. A PW Doppler sample volume is placed at the mitral valve leaflet tips to evaluate left ventricular diastolic function which reveals prolonged isovolumic relaxation time, prolonged deceleration time, decreased E-wave to A-

wave ratio on mitral inflow. A PW Doppler study at pulmonary vein reveals increased S-wave to D-wave ratio and pulmonary vein 'a'-wave reversal duration prolonged and velocity increased (Klein et al. 1994). Because the path physiologic mechanism in diastolic heart failure includes a high diastolic pressure-volume relationship, the therapy has been directed at reducing filling pressure by decreasing end-diastolic volume, reducing heart rate and treating hypertension with drugs that also cause regression of left ventricular hypertrophy (Paul et al. 1996). The American College of Cardiology/American Heart Association (ACA/AHA) task force divides pharmacologic treatment into three classifications for the management of diastolic heart failure. Class I refer to drugs that are always indicated, such as diuretics and nitrates and drugs suppressing atrioventricular conduction. Class II agents are acceptable; however, their efficacy is uncertain. These include calcium-channel blocker B-blocker, angiotensin converting enzyme (ACE) inhibitor. Class III drugs are not indicated and include drugs with positive isotropic effects. Although prognosis is better with diastolic dysfunction than with systolic dysfunction, morbidity and mortality continue to be high in elderly patients. The reported annual mortality rate for patients with heart failure and preserved left ventricular systolic failure varies from 3 to 25 percent (Vasan et al. 1995). The syndrome of diastolic heart failure is common but neglected event in the evaluation of hypertensive patients. The signs and symptoms may be similar to those in patients with systolic heart failure. The prognosis may be different due to heterogeneity in the parent population. There is no uniformity in how to diagnose and how to treat patients with heart failure with diastolic dysfunction. Therefore, the present study was undertaken to evaluate the left ventricular diastolic dysfunction in congestive heart failure resulting from systemic hypertension in our population.

Objectives

General Objective:

- i) To assess the prevalence of diastolic dysfunction in congestive heart failure resulting from systemic hypertension.

Specific objectives:

- i) Assessment of diastolic dysfunction in congestive heart failure due to hypertension by deferent echocardiography methods.
- ii) See the correlation between hypertrophy and ischaemia in diastolic dysfunction.

MATERIALS AND METHODS

The present prospective observational study was undertaken in Shaheed Shaikh Abu-Naser Specialized Hospital, Khulna, Bangladesh to evaluate left ventricular diastolic dysfunction in

congestive heart failure resulting from systemic hypertension during the period from January 2017 to December 2018. Fifty randomly selected hypertensive patients of congestive heart failure (CHF) with diastolic dysfunction were taken from indoor departments of the above centers; Informed consents were taken from the patients. Detailed history and physical examination findings were recorded in study report sheet (Appendix-I). ECG, chest X-ray two-dimensional and M-mode echocardiography reports were recorded on the same sheet. Doppler echocardiography was done by a cardiologist and evaluation involved pulse-wave Doppler sampling of mitral inflow (tips of leaflets) and pulmonary vein inflow (right upper vein 1-2 cm deep). Flow patterns across the mitral inflow are E/A ratio, deceleration time (m/s), isovolumic relaxation time (m/s) and flow patterns across pulmonary inflow S/D ratio, atrial reversal (AR) velocity, Ad/ARd ratio (Fig. 6 and 7). Eligible patients underwent stress testing and coronary angiography. Initially 320 cases were selected for the study with CHF and 210 were eliminated on the basis of ejection fraction (EF) <0.5. Of the 110 remaining cases, 32 were excluded because of rheumatic heart disease (RHD), hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM). The rest 78 were hypertensive, of whom 28 were rejected because of poor echocardiogram, or because they were incompatible of stress testing due to unfit (Fig. 9). Data have been expressed in frequency, percentage and mean \pm SD as applicable. Comparison between groups was done by Chi-square test, Student's t test and Fisher exact test, as applicable. Data were analyzed by computer-based statistical software. P value <0.05 was taken as significant.

Inclusion criteria

- Patients with history of hypertension for >5 years
- Patients with dyspnoea of cardiac origin (NYHA class II, III and IV)
- Pulmonary oedema verified by CXR-P/A view
- Echocardiographically determined ejection fraction \geq 50%
- Sinus rhythm.

Exclusion criteria

- Secondary hypertension
- History of angina or myocardial infarction
- History of diabetes mellitus, chronic renal failure and hypertrophic
- History of rheumatic fever and rheumatic heart disease, congested heart disease and any systemic diseases that causes left ventricular hypertrophy
- Any endocardial, myocardial or pericardial disease
- Poor echo-windows.

RESULTS

A total 320 patients were screened with congestive heart failure, among them 210 were rejected because of ejection fraction <50, i.e. systolic dysfunction

(65%), 32 were excluded due to rheumatic heart disease, ischaemic heart disease, hypertrophic and dilated cardiomyopathy and 28 patients were eliminated because of poor echo-window and physical unfit and thus 50 patients with diastolic dysfunction (16%) with hypertensive were included in the study [Figure 9], though total number of diastolic dysfunction were 110 (35%). [Table 2] shows the age and sex distribution with highest frequency in the age group 61-70 years, comprising 32 percent and 51-60 years 28 percent, 40-50 year 24 percent, 71 + years 8 percent and 30-40 years 6 percent in descending order. The patients were classified into two groups according to the degree of echocardiographic hypertrophy in group I (26 patients with a mass/volume ratio > 1.8) and group II (24 patients with M/V ratio < 1.8). Table shows age <50 were 24 percent of which 8 from group I (30.77%) and 4 from group II (16.67%); age >50 were 76 percent of which 18 from group I (69.23%) and 20 from group II (83.33%). Diastolic dysfunction of group I and group II patients according to sex, presented male were 31 (62%) of which 19 from group I (73.08%) and 12 from group II (50%), female were 19 (38%) of which 7 from group I and 12 from group II (50%). Table shows types of diastolic dysfunction, with sample volume position at mitral inflow with tips of leaflets. There are 3 types of diastolic dysfunction -impaired relaxation (IR), pseudonormalization (PN) and restricted filling (RF). By E/A ratio, cases of various types are 20 (IR), 10 (PN) and 20 (EF); by deceleration time (tDec), 19 (IR), 10 (PN) and 21 (RF), by IVRT are 19 (IR), 11 (PN) and 20 (RF). Table also shows types of diastolic dysfunction with sample volume position at right upper pulmonary vein inflow - impaired relaxation are easily diagnosed by S/D ratio > 1, but the differentiation between pseudonormalization and restricted filling is difficult unless compared with mitral flow PWD, especially tDec and IVRT. By S/D ratio, cases of various types are 20 (IR), 10 (PN) and 20 (RF); by AR velocity are 19 (IR), 10 (PN), 21 (RF) and by Ad/ARd are 19 (IR), 11 (PN) and 20 (RF). Cardiac catheterization has been done in 22 cases out of 50 cases of diastolic dysfunction. Among 22 cases, diastolic dysfunction was found in 18 cases (LVEDP > 15 mmHg) and left ventricular end-diastolic pressure was normal in 4 cases, all of them were of impaired relaxation variety. Therefore, Doppler echocardiographic estimation is comparable (significant) with cardiac catheterization estimation. ETT were positive in 4 patients in group I and 18 patients of group II, whereas ETT were negative in 22 patients in group I and 6 patients of group II. So, group I show more negativity than group II. Among 22 ETT positive patients, group I consists of 4 patients, of which 2 are CAG positive and 2 are negative. Group II consists of 18 patients of which 16 are positive and 2 are negative. According to degree of hypertrophy,

NYHA class II dyspnoea in 26 cases of group I and in 24 cases of group II. Mean age is 53.65 years with SD 11.28 in group I and 57.29 with SD 9.44 in group II. Males were 31 and female 19. Mean heart rate \pm SD in group I is 80.92 \pm 8.03 and 78.75 \pm 6.18 in group II. S3 were mainly found in group II, whereas S4 i group I. Both systolic and diastolic blood pressure is higher in group II, LVH were more positive in group I, cardiomegaly in group II, ejection fraction more in group I and duration of hypertension were almost equal.

DISCUSSION

This prospective observational study was undertaken to evaluate left ventricular diastolic dysfunction in congestive heart failure resulting from systemic hypertension. As the sample size was not very large, they may not be representative of all hypertensive heart diseases with congestive heart failure in the community. In the present study, age of the study population ranged from 30 to 75 years, with incidence in 61-70 years comprising 32 percent, followed by 51-60 years 28 percent, 41-50 years 24 percent, 71-75 years 8 percent and 30-40 years 6 percent. Paul and Gheorghideet al.^[1] also found diastolic dysfunction more in elderly (50 to 60 years) group. Although by standard echocardiographic criteria is reversal of E/A ratio favours the diagnosis of diastolic dysfunction, Marantz et al.^[2] (1994) have shown that this inversion may be normal in older subjects. So, it is important to use the other

parameters in elderly subjects. In the series of 50 hypertensive patients with LV failure with normal ejection fraction, it is possible to divide into two groups: group I with a mass/volume ratio > 1.8 whose dominant character is the high degree of reactive hypertrophy more in the elderly; and group II with a mass/volume ratio <1.8 whose dominant character is high rate of ischaemia, also more in elderly group. Leftventricular mass (LVM) is estimated using M-mode at end-diastole, using the measurement of IV septal thickness (IVST), posterior wall thickness (PWT) and left ventricular diameter (LVID) as follows: $LVM = 0.8 (1.04 f(ST + PWT + LVID))^3 - LVID^3$ + 0.6 g where, 1.04 is the specific gravity of myocardium; 0.8 is the correction factor added since anatomic weight would otherwise be overestimated by approximately 20 percent (Lima 1998). LV volumes were calculated on the basis of end-systole and end-diastole diameter. To evaluate the Influence of the ventricular mass and rate of regional ischemia, the cutting point is mass/volume ratio is 1.8 with maximal level of differentiation between hypertrophy and ischaemia (Miguel et.al. 1993).^[3] Diastolic dysfunction was common in male (62%) than female (38%). Less number of female patients was involved in the study as small number of female patients attends the hospital for treatment. High incidence of hypertrophy were found in male patients in comparison to female (73.08% vs 26.92%) but incidence of ischaemia were equal in both male and female (50% vs 50%). The most significant findings according to echocardiographic left ventricular hypertrophy were increased left ventricular posterior wall thickness and interventricularseptal thickness, decreased LV end-diastolic and end-systolic diameter, increased LV mass and higher ejection fraction in group I (hypertrophic group) than in group II (ischaemic group). These results are somewhat similar to the results described by Topol and Arail (1985) and Miguel et al. (1993).^[3,4] Duration of hypertension did not correlate with the incidence of diastolic dysfunction and there was no significant difference between group I and group II. There was no published data both at home and abroad to compare the relationship between duration of hypertension and incidence of diastolic dysfunction with the present study. Doppler patterns of diastolic dysfunction include normal diastolic function, impaired relaxation, pseudonormal filling and restricted filling. These patterns evolve from one to another in a single individual with changes in disease evaluation, treatment and loading condition as described by Gerald et al. (1996).^[5] Impaired relaxation is typically manifested by E/A ratio <1, an increased deceleration time (tDec) and an increased isovolumetric relaxation time (IVRT) with sample volume position at mitral flow. Pulmonary venous flow is also abnormal characterized by increased S/D ratio, decreased atrial reversal (AR)

velocity and increased ratio of atrial duration (Ad) to atrial reversal duration (ARd). At this state, patient is usually mildly symptomatic with exertional activities with normal filling pressure and normal LA dimension. Pseudonormalization refers to normal appearance of mitral flow (E: A ratio between 1.0 and 1.5, tDec 180-220, IVRT 80-100) and pulmonary venous flow (S:D ratio <1, AR velocity >25, Ad/ARd<1). At stage II, the effects of impaired relaxation on early diastolic filling become opposed by the elevated left atrial pressure and the early diastolic transmitral pressure gradient and mitral flow velocity pattern return to normal. This phenomenon is called pseudonormalization to indicate that although left ventricular filling (appears normal, significant abnormalities of diastolic functions are present. In most cases, left atrial and left ventricular and diastolic filling pressure are elevated, the left atrium is increased in size and patients often complain of exertional dyspnoea (Appleton et al. 1988; Klein et al. 1994; Ishida et al. 1986).^[6-10] The restricted filling pattern is characterized by increased E: A ratio, decreased tDec, decreased IVRT on mitral flow, and decreased S:D ratio, increased AR velocity and Ad/ARd ratio is decreased on pulmonary venous flow. At stage III, it represents a severe decrease in LV chamber compliance. Diastolic filling pressures are elevated and patients are markedly symptomatic and demonstrate a severely reduced functional capacity. The left atrium is dilated and hypocontractile (Appleton et al. 1988).^[6] Cardiac catheterization were done only in 22 cases, of which 18 showed elevated LV end-diastolic pressure more than 15 mmHg and 4 showed normal LV end-diastolic pressure, all of them showed diastolic dysfunction by Doppler assessment. Thus, Doppler evaluation provides a noninvasive, safe and rapid bedside alternative to cardiac catheterization for the assessment of LV diastolic dysfunction (Kaul 1991).^[11] Exercise tolerance tests were done in all cases that were physically active. Out of 50 cases, 22 were positive for provokable myocardial ischaemia. Among 22, group I showed 4 positive cases and group II showed 18 positive cases. Thus, there were two distinct subgroups: group I characterized by high degree of reactive hypertrophy and low incidence of ischaemia and group II with only moderate hypertrophy and high risk of ischaemia. These findings correlated well with the results of Iriate et al. (1993).^[12] Coronary angiogram (CAG) was performed in 22 ETT positive cases, out of which, 2 patients of group I was positive, 2 were normal. And 16 patients of group II were positive, 2 were normal. Four patients, 2 from group I and 2 from group II were found to have provokable myocardial ischaemia but CAG were normal. The ETT positive but CAG negative cases constitute patients of syndrome X and their ischaemia may have been caused by hypertensive microangiopathy

(Fragasnoet al. 1997).^[13] There was no significant difference between groups for NYHA class, age, sex, heart rate, systolic blood pressure. A fourth sound was more common in group II, whereas the third sound was more frequent in group II. ECG evidenced LHV were more frequent in group I than group II, CXR evidenced cardiomegaly in group II than group I. The findings correlate well with the study of Iriate et al. (1993).^[12] Our findings indicate that patients with diastolic dysfunction in hypertensive heart disease with CHF with normal ejection presented in two ways: one characterized by severe hypertrophy and the other by a high rate of ischaemia. But their clinical profile was uniform and indistinguishable from CHF due to depressed LV systolic function as reported by Echeverria et al. (1983),^[14] Dougherty et al. (1984),^[15] Souferet et al. (1985) and Kessheret et al. (1988).^[16,17] Our study showed the possible influence of degree of hypertrophy or of regional myocardial ischaemia on the pathophysiologic or clinical characteristics of hypertensive heart disease results in CHF with normal ejection fraction. Therapy should be aimed at pathophysiologic regression of the hypertrophy in the first case and at improvement of ischaemia in the second case. Doppler echocardiography is an important tool in the case of such patients. It provides a noninvasive, safe and rapid bedside alternative to cardiac catheterization for the assessment of ventricular diastolic function.

Limitations of the Study

Present study conducted in one centre with small sample size, which can't reflect the scenarios of the whole country.

CONCLUSION

Congestive heart failure from left ventricular diastolic dysfunction in hypertensive patients presents with two different profiles: one characterized by severe hypertrophy and low incidence of ischaemia and the other by high rate of myocardial regional ischaemia and low incidence of hypertrophy. They present a uniform clinical pattern, and they are indistinguishable from CHF due to low ejection fraction. Therapy should be aimed at pathophysiologic regression of the hypertrophy in the first case and at improvement of the ischaemia in the second.
